# Too Afraid to Learn: Attitudes towards Statistics as a Barrier to Learning Statistics and to Acquiring Quantitative Skills

Koen Slootmaeckers

Bart Kerremans and Johan Adriaensen

*KU Leuven, University of Leuven*

Quantitative skills are important for studying and understanding social reality. Political science students, however, experience difficulties in acquiring and retaining such skills. Fear of statistics has often been listed among the major causes for this problem. This study aims at understanding the underlying factors for this anxiety and proposes a potential remedy. More specifically, we advocate the integration of quantitative material into non-methodological courses. After assessing the influence of dispositional, course-related and person-related factors on the attitudes towards statistics among political science students, we provide insights into the relation between these attitudes on the one hand and the learning and retention of statistics skills on the other. Our results indicate that a curriculum-wide approach to normalise the use of quantitative methods can not only foster interest in statistics but also foster retention of the acquired skills.

**Keywords:** statistics anxiety; quantitative skills; statistics teaching; statistics retention

## Introduction

How can we help political science students to acquire numeric and statistical skills? In society, numbers are omnipresent. Media, corporations and politicians overwhelm people with quantitative information. Numeric skills are important to avoid deception and to function in society. As a consequence, these skills are also important for political science students to grasp and understand social reality (Hulsizer and Woolf, 2009). Students, however, tend to avoid quantitative methods and even fear them.<sup>1</sup> If quantitative skills are becoming more important in society and political science, and we wish to help students to acquire them, we need to understand this statistics anxiety and its impact on statistics learning better. This article seeks to address two questions: to what extent is statistics anxiety a barrier preventing students from retaining their previously acquired statistical skills? And more importantly, what kind of approach is needed to remove this barrier?

In order to address this problem, we proceed in two steps. First we inquire into the various antecedents of statistical anxiety. On the basis of this discussion, we propose to integrate quantitative methods in substantive courses as a potential remedy. In a second step, we test whether the suggested innovation also fosters retention of the acquired skills.

## On the causes and effects of statistics anxiety

Students perceive statistics as 'the worst course taken in College' (Wiberg, 2009, p. 1) or as 'inherently uninteresting, quite difficult and, like immunization injections they received as children, a necessary but quite unpleasant aspect of growing up' (Bridges et al., 1998, p. 15). Statistics courses are not only a negative experience, but students are often 'scared to death' by the idea (Bradstreet, 1996; Onwuegbuzie and Wilson, 2003). Anthony Onwuegbuzie and Vicki Wilson (2003, p. 196) describe statistics anxiety as the 'anxiety that occurs when a student encounters statistics in any form or at any level'. This anxiety does not necessarily stem from bad training or insufficient skills (Pan and Tang, 2004), but from students' misperceptions both about statistics and about their (lack of) mathematical skills, from warnings from their peers or from the 'horror stories' they have heard (Bridges et al., 1998; Hulsizer and Woolf, 2009; Onwuegbuzie and Wilson, 2003; Pan and Tang, 2004).

Statistical anxiety is not without consequences for the ability of students to acquire statistical skills and, once acquired, to retain them (Elmore, Lewis and Bay, 1993; Emmioğlu and Çapa-Aydin, 2011; Onwuegbuzie, 2003). A meta-analysis conducted by Esma Emmioğlu and Yesim Çapa-Aydin (2011) indicates, for instance, that a positive relationship exists between students' affect towards statistics and their perception of their cognitive competence on the one hand, and obtained grades in statistics tests on the other. Their analysis also shows a positive but small effect of the valuing of statistics and of the perception of difficulty, with all attitudes coded such that a higher score represents a more positive attitude.

There is a vast amount of research on the antecedents of statistics anxiety (Pan and Tang, 2004; Papanastasiou and Zembylas, 2008). Factors inducing such anxiety are often classified in three categories: dispositional, course-related and person-related factors (Baloğlu, 2003; Onwuegbuzie and Wilson, 2003; Pan and Tang, 2004). The 'dispositional factors' (Onwuegbuzie and Wilson, 2003; Pan and Tang, 2004) refer to the psychological and emotional characteristics of students, such as attitudes, perceptions and (perceived mathematical) self-concept. Negative scores on these factors are generally related to more statistics anxiety. The course-related elements also referred to as 'situational factors' result immediately from statistics courses. These can be the nature of the course (Onwuegbuzie and Wilson, 2003), prior knowledge, statistical course grades (Papanastasiou and Zembylas, 2008) and course and/or teacher evaluation (Baloğlu, 2003; Onwuegbuzie and Wilson, 2003; Papanastasiou and Zembylas, 2008). These course-related factors extend to prior experiences with mathematical courses and grades as well (Onwuegbuzie and Wilson, 2003; Zeidner, 1991). Negative experiences tend to increase statistics anxieties, particularly when students are confronted with mandatory courses. Finally, the person-related antecedents (also referred to as 'environmental' factors) are the socio-demographic characteristics, for example gender, age and educational level, of the students. Female students suffer more from statistics anxiety than male students do, and the same holds for younger students as compared to older ones (Baloğlu, 2003; Onwuegbuzie and Wilson, 2003). It is clear that dispositional or person-related antecedents are largely out of our control. If we wish to remedy statistics anxiety we need to target the course-related elements.

A look at the literature indicates that whenever studies suggest remedies for statistics anxiety and its impact on statistics learning, a strong focus exists on statistics or research methods courses (Elmore, Lewis and Bay, 1993; Emmioğlu and Çapa-Aydin, 2011; Onwuegbuzie, 2003). The implicit underlying assumption seems to be that such courses and their reform

should play a prominent role in remedying statistical anxiety and from there on statistical achievement and retention. While there is much credence to such an approach, it can only remedy the problem in so far as the class context allows for it. Statistics teachers may feel very uncomfortable about reforming their courses. Characteristics of the student group that such teachers meet in their classes (such as the size of the group and variation in mathematical skills among students) may even make it impossible. Our political science programme fits into this latter category. First, statistics courses tend to be taught to very large student groups (>300 students) from over 13 different programmes, among which political science students form a minority. Activating students in such a context is extremely difficult, as is the provision of appealing examples. Second, mandatory statistical and research methods courses tend to be front-loaded in our programmes. In multi-year programmes this means that students encounter statistics in the first semesters of their training. After that, they can easily escape from them, which most students do. Only 5 per cent of them opt for an advanced statistics course when exposed to the choice between such a course and one on advanced qualitative research methods in the third year of their training. For the remainder, no statistics courses are on offer. There are however some elective non-methodological courses in which teachers make use of statistical analysis.

In addition, as statistics courses have a bad reputation among many students, enrolment in the mandatory statistics courses is already sufficient to trigger high anxiety levels. Overcoming this effect by reforming these courses may be extremely difficult in the short to medium term, given the negative aura that tends to surround such courses.

A way out of this may then consist of an anxiety-reducing approach which transcends the statistics or research methods courses. Building on William Markham's (1991) call for introducing quantitative methods in introductory courses, and on the more recent plea of Katharine Adeney and Sean Carey (2009; 2011) to contextualise quantitative methods in political science education, we investigate whether using statistics in non-methodological courses can be a remedy for the statistics anxiety problem. In order to assess the potential of this approach, we propose an extra course-related factor: the acquisition of statistical skills outside statistics courses. By doing so, we address an important lacuna: until now an explicit measurement of the impact that such an approach can have on students' ability to learn statistics has been absent in the literature.

## Data and measures

In light of the Educational Project on Overcoming Statistics Anxiety (EPOS) initiated in the Political Science programme of our university, we conducted a survey with all students enrolled in that programme. In our project, we seek to integrate a learning trajectory on quantitative methods into non-methodological courses. This is achieved by the development of learning activities for the various courses involved. The systematic incorporation of such activities results in a gradual and repeated exposure of students to quantitative methods. For more information on the project see <http://soc.kuleuven.be/epos>. As our article focuses on the retention of prior acquired statistical skills, analyses are based on the data from our third year (last year of the Bachelor's programme;  $n = 41$ , response rate of 77.36 per cent) and Master's programme students ( $n = 116$ , response rate of 63.74 per cent). At the start of the project, we administered a web survey for both groups. This survey is based on the Survey of Attitudes Toward Statistics (SATS-36) (Schau et al., 1995), and contained additional questions about prior experiences with statistics, as well as questions on socio-demographic parameters.

The SATS-36 of Candace Schau et al. (1995) consists of six sub-components: Affect, Cognitive Competence, Value, Difficulty, Interest and Effort. We dropped the Effort sub-scale because the students in question are not enrolled in a statistics course. A factor analysis on the reduced version of SATS-36 failed to distinguish the Affect sub-scale from the other factors.<sup>2</sup> The four obtained factors, however, can still be interpreted using the original scoring scheme of Schau (2005). The Interest sub-scale means 'students' level of individual interest in statistics' (Cronbach's alpha = 0.87). Difficulty can be understood as: 'students' attitudes about the difficulty of statistics as a subject' (Cronbach's alpha = 0.74). The Value sub-scale can be defined as 'students' attitudes about the usefulness, relevance, and worth of statistics in personal and professional life' (Cronbach's alpha = 0.81). Finally, Cognitive Competence means 'students' attitudes about their intellectual knowledge and skills when applied to statistics' (Cronbach's alpha = 0.82). For each factor we reversed negative statements and constructed a mean scale, with range 1–7, '1' meaning a negative attitude and '7' meaning a positive attitude towards statistics. The four factors were used as dependent variables in our analyses of the antecedents of statistical anxiety (see Table 1). The measurement of these antecedents is presented below.

For the dispositional factors we included a measure for mathematics self-concept, that is, students' perception about themselves in relation to mathematics, and for the perception of use of statistics in their future career. Regarding the latter, students were asked to answer on a 7-point Likert scale to what extent they think they will use statistics in their future job, with 7 meaning 'I'll use statistics frequently in my future job'. For mathematical self-concept, students were asked to evaluate their own statistics skills on a 7-point Likert scale.

The course-related (situational) factors probed the students' experience with statistics, both in a subjective and an objective sense. For subjective experience, students were asked to state how experienced they are with statistics on a 7-point Likert scale, with 7 meaning very experienced. Objective experience was measured by the number of statistics courses taken in higher education. Finally, for person-related (environmental) factors, gender, age and year of the programme the students are enrolled in were included in the model.

For our anxiety-reducing approach of introducing statistics in non-methodological courses, we used the following measurements: for Quantitative Material in Non-methodological Courses (QMNC), we asked students to self-report their encounters with statistics in non-methodological courses on a 5-point Likert scale with 5 meaning frequent encounters. As data gathering took place at the start of the project – before quantitative learning activities were developed and implemented – the variation on this variable results from the students' selection of electives. In the later years, a number of non-methodological electives already, although not systematically, incorporate quantitative methods. The EPOS project seeks to systematise this practice and to spread it to courses where quantitative data are not being used. In our current sample, 25 per cent of the students indicated that they regularly encountered quantitative material in their courses whereas 20 per cent almost never shared such experience. The majority of responding students (54 per cent) fell in between both categories, selecting sometimes as the most appropriate response to our question.

In the first set of analyses of this article, we use the antecedents and the measurement for QMNC as independent variables to explain the variation in statistics anxiety. In the second set of analyses we use both the antecedents and the statistics anxiety measures as independent variables to understand the retention of statistical skills.

Unlike other studies focusing on the effects of statistics anxiety on the learning of statistics which deal with the achievements in statistics courses, we focus on the retention of such skills. Given the growing importance of statistics, retention of quantitative skills should be a goal of higher education, as it ensures that students are well prepared for their future careers. To measure statistics retention, we constructed a second battery of questions inquiring into students' statistical skills. This happened in close collaboration with educational scientists from our university. The questions were based on exercises from the ARTIST project (<https://apps3.cehd.umn.edu/artist/index.html>); the Dutch translation of Garfield's questionnaire 'Statistical Reasoning Assessment' (Vanhoof et al., 2009); and the practice book of Bruce Moore and George McCabe (2007). The topics range from the interpretation of OLS regression results and significance tests to probability theory and histograms. From the responses to these questions a variable was computed which represents the percentage of correct responses relative to the number of answered questions (90 per cent of the students answered 20 questions out of 25). We interpret this variable as 'statistics retention', as almost all of the sampled students were not enrolled for a quantitative methods course in one (third Bachelor's) or two (Master's) years preceding the survey. To our knowledge, we are among the first to study the relation between attitudes towards statistics and the retention of statistical skills in political science.

## Results

Table 1 shows the results of the first set of analyses, that is, the models regressing statistics anxiety on the antecedents. Whereas model 1 includes the full array of explanatory variables, we decided to run an additional set of regressions (for the Value and Cognitive Competence factors only) excluding the dispositional factors where the conceptual overlap with the dependent variable became problematic. Where relevant, we only discuss the results from model 2.

Looking at the effect of the dispositional factors, the results show that the perception of statistical skills has a positive effect on Interest, Difficulty and Value. Whereas such perceptions promote a larger individual interest in statistics (and a recognition of its value), they also reduce the conviction that statistics is difficult. The perception of the future use of statistics impacts positively on Interest, Difficulty and Cognitive Competence. The recognition that statistics learning has an added value professionally reduces students' mental barriers with respect to statistics.

With regard to the course-related factors, the results show that subjective experience has a negative effect on Interest and Difficulty. Students who report more experience with statistics are generally less interested in the subject and generally find it more difficult. The number of statistics courses taken, on the other hand, does not have an effect on the attitudes towards statistics except for Cognitive Competence.

Regarding the person-related factors, we find no impact of age on statistics anxiety. On the other hand, female students tend to be more pessimistic about their cognitive competence and the difficulty of statistics. They also value statistics less than their male colleagues do.

Looking at the effect of our proposed remedy for statistics anxiety (and retention of statistics; see below), we find that, contrary to the course-related factors, encountering quantitative methods during substantive (non-methodological) courses has a positive effect on both the interest in and the value attributed to statistics. These findings point to the potential of

explicitly introducing statistics in non-methodological courses for remedying students' fear of statistics, and potentially for the retention of previously acquired skills.

In our second set of analyses (see Table 2), we first regress the retention of statistical skills on the four factors of statistical anxiety, controlling for the antecedents (see model 3, Table 2). In the following model (model 4), we add the measure for QMNC to the model. In doing so we can assess the extra explanatory power of QMNC for the retention of statistical skills. Given our interest in improving students' ability to retain statistics skills, the analyses presented in Table 2 are most central to our argument. We discuss the results by comparing both models.

In model 3, only three variables prove to be statistically significant: interest, difficulty and subjective experience with statistics.<sup>3</sup> The results are intuitive and in line with the existing literature. Higher interest in statistics, perceptions of statistics as being less difficult, and more subjective experience with statistics promote retention. The addition of experience with QMNC clearly affects these outcomes, as model 4 indicates. The QMNC factor itself is statistically significant and positively related. Students reporting more encounters with statistics in non-methodological courses score higher, generally speaking, on the statistical retention variable.

Next to the significance of the QMNC variable, we find that including this measure in the model has some important repercussions for the model as well. More specifically, we find QMNC to be a suppressor variable for the perception of statistical skills. By including QMNC in the model, the effect of the perception of statistical skills becomes significant, revealing that students who believe they have good statistical skills generally score lower on the retention variable. Additionally, we find that QMNC is slightly redundant to Interest. By including QMNC, the 'interest' variable becomes less significant (from  $P < 0.05$  to  $P < 0.10$ ) and its effect decreases slightly. The encounters with statistics in non-methodological courses thus account for part of the effect of interest on the retention of statistical skills.

From these results some important observations can be derived. First, it is clear that an approach that includes the use of quantitative material in non-methodological courses strongly promotes the ability to retain statistics skills. With an extra explanatory power of nearly 7 per cent (cf. change in  $R^2$ ), we conclude that QMNC is an important factor to take into account when working on statistics retention. At the same time, however, QMNC is not a panacea that solves all problems. Difficulty continues to affect statistics retention directly as much as students' perceptions of their statistical skills do. Taking the effect of both of these factors into account, the results indicate that when addressing students' perceptions of the difficulty of statistics, we need to remain aware that too much confidence in one's abilities to do statistics reduces the retention of statistics skills (Keeley, Zayac and Correia, 2008).

## Conclusion

The aim of this article was to find out how we can help our political science students in their ability to learn and retain statistics skills. We did so by first exploring the different antecedents of statistics anxiety. We then analysed the relation between students' experience with QMNC and students' retention of statistics skills. The results, which are in line with existing findings, show that the dispositional, course-related and person-related antecedents have their influence on students' attitudes towards statistics. The analyses also show that the number of statistics courses taken has no influence on students' statistics retention; it is the extent to which quantitative material is used in non-methodological (substantive) courses that positively impacts on such retention. This provides an argument not to limit the promotion of statistics learning to reforms of statistics or research methods courses as such, but to promote it by intervening in the non-methodological parts of the political science curriculum as well.

The use of quantitative material in non-methodological courses can be a double-edged sword, however, which requires the fine-tuned use of such material. Although our analyses show that such use has a strong potential to impact positively on students' ability to retain their statistical skills, they may also suggest that badly shaped use of QMNC may definitively turn off students who already have a complex relationship with statistics, both on the basis of the perception of their own skills and their perception of statistics as a difficult topic. The use of quantitative material in non-methodological courses is, therefore, not a panacea. It requires full attention to the kinds of underlying problems that trigger statistics anxiety and low statistics learning.
